Public Health Consequences of Use of Antimicrobial Agents in Food Animals in the United States

ALICIA D. ANDERSON, JENNIFER M. NELSON, SHANNON ROSSITER, and FREDERICK J. ANGULO

ABSTRACT

The use of antimicrobial agents in food animals has caused concern regarding the impact these uses have on human health. Use of antimicrobial agents in animals and humans results in the emergence and dissemination of resistant bacteria. Resistant bacteria from food animals may be passed through the food chain to humans resulting in resistant infections. Increasing resistance to antimicrobial agents that are important in the treatment of human diseases, such as fluoroquinolones and third-generation cephalosporins for the treatment of Salmonella and Campylobacter infections, has significant public health implications. Efforts to mitigate the effects of increasing resistance require collaboration by several partners, including the farming, veterinary, medical, and public health communities.

INTRODUCTION

Antimicrobial agents have been used in livestock and poultry since the early 1950s to treat infections and improve growth and feed efficiency. The amount of antimicrobial agents used in food animals (cattle, chickens, pigs, and turkeys) in the United States is unknown; however, a substantial portion given to these animals is for nontherapeutic uses (i.e., uses in the absence of disease) such as growth promotion, a practice that is becoming increasingly controversial. The use of antimicrobial agents in food animals that have a human analog increases the likelihood that bacterial pathogens that have food animal reservoirs will develop cross-resistance to antimicrobial agents used in human medicine. The World Health Organization, following a series of consultations in 1997, 1999, and 2000, has recommended that, unless a risk-based evaluation demonstrates their safety, the use of antimicrobial agents in food animals for growth promotion that belong to classes of antimicrobial agents used in humans should be terminated. Similar recommendations to discontinue the use of human antimicrobial agents as growth promoters in food animals have been made by several independent organizations in the United States, including the Alliance of Prudent Use of Antibiotics in 2002 and the distinguished Institute of Medicine of the National Academies in 2003.

Several European countries have already taken steps toward this goal. In 1998, the European Union banned four growth promoters (tylosin, spiramycin, bacitracin, and virginiamycin) because of their structural relatedness to antimicrobial agents used in human medicine. In that same year, chicken farmers and beef producers in Denmark voluntarily stopped using antimicrobial agents as growth promoters; swine farmers followed suit in 1999. This ban has reduced the total volume of antimicrobial agents used in food animals in Denmark by 60% (from 206 to 81 tons per year). Studies to investigate the influence of the ban have shown no negative consequence for farmers’ profits or animal health in broiler chickens. Similar conclusions were reported in fattening pigs, although diarrhea in weaned piglets has required other interventions, such as improved feeding and weaning procedures. In Sweden, antimicrobial agents were banned as growth promoters in 1986, decreasing the usage of antimicrobial agents in food animals by 55% and demonstrating the ability to achieve competitive production results in the absence of growth promotants. The effects of discontinuation of antimicrobial agents as growth promoters in these European countries have been a decrease in antibiotic resistance in animals, food products, and humans.

Clinicians should be aware that antimicrobial resistance is increasing in foodborne pathogens such as Salmonella and Campylobacter and that patients who are taking antimicrobial
agents for any reason are at increased risk for acquiring antimicrobial-resistant foodborne infections. The increasing prevalence of antimicrobial resistance among these pathogens also increases the potential for treatment failures and other adverse outcomes, including death. Appropriate use of antimicrobial agents in humans and food animals is necessary to maintain their effectiveness and reduce the potential for spread of resistant organisms. While therapeutic usage of antimicrobial agents in food animals is important for promoting animal health, it is vital that the long-term effectiveness of antimicrobial agents used in human medicine be preserved. This report presents current surveillance information on the frequency of resistant foodborne infections in the United States, reviews scientific evidence linking antimicrobial agent usage in food animals to resistant foodborne infections in humans, and makes recommendations for measures to protect public health.

USE OF ANTIMICROBIAL AGENTS IN FOOD ANIMALS IN THE UNITED STATES

At least 17 classes of antimicrobial agents are approved for growth promotion and feed efficiency in the United States, including tetracyclines, penicillins, macrolides, lincomycin (analog of clindamycin), and virginiamycin (analog of quinupristin/dalfopristin). To understand the human health consequences of the use of antimicrobial agents in food animals, it is important to evaluate the quantity of antimicrobial agents used in food animals in the United States. Unfortunately, although reporting systems recently have been implemented in several European countries, no reporting system exists for the quantity of antimicrobial agents used in food animals in the United States. The Animal Health Institute, which reportedly represents 80% of the companies that produce antimicrobial agents for animals in the United States, has estimated that their member companies produced 18 million pounds of antimicrobial agents for therapeutic and nontherapeutic (growth promotion and disease prevention) use in food animals in the United States in 1999. An alternative report, provided by the Union of Concerned Scientists in 2001, estimated that 29 million pounds of antimicrobial agents are used in food animals annually in the United States. At least 17 classes of antimicrobial agents are approved for growth promotion and feed efficiency in the United States, including tetracyclines, penicillins, macrolides, lincomycin (analog of clindamycin), and virginiamycin (analog of quinupristin/dalfopristin). To understand the human health consequences of the use of antimicrobial agents in food animals, it is important to evaluate the quantity of antimicrobial agents used in food animals in the United States. Unfortunately, although reporting systems recently have been implemented in several European countries, no reporting system exists for the quantity of antimicrobial agents used in food animals in the United States. The Animal Health Institute, which reportedly represents 80% of the companies that produce antimicrobial agents for animals in the United States, has estimated that their member companies produced 18 million pounds of antimicrobial agents for therapeutic and nontherapeutic (growth promotion and disease prevention) use in food animals in the United States in 1999. An alternative report, provided by the Union of Concerned Scientists in 2001, estimated that 29 million pounds of antimicrobial agents are used in food animals annually in the United States.

As in human medicine, the use of antimicrobial agents in food animals creates a selective pressure for the emergence and dissemination of antimicrobial-resistant pathogens, including animal pathogens, human pathogens that have food animal reservoirs, and other bacteria that are present in food animals. These resistant bacteria may be transferred to humans either through the food supply or by direct contact with animals. The transfer of resistant bacteria from food animals to humans is most evident in human bacterial pathogens that have food animal reservoirs, such as Campylobacter, which has a reservoir in chickens and turkeys, and Salmonella, which has reservoirs in cattle, chickens, pigs, and turkeys. To monitor antimicrobial resistance in foodborne enteric pathogens, the National Antimicrobial Resistance Monitoring System (NARMS) for Enteric Bacteria was launched in 1996. NARMS is a collaboration among the Centers for Disease Control and Prevention (CDC), the Food and Drug Administration (FDA)—Center for Veterinary Medicine, the United States Department of Agriculture (USDA), and state and local health departments [http://www.cdc.gov/narms]. In addition to NARMS, the Foodborne Diseases Active Surveillance Network (FoodNet) conducts population-based studies to estimate the burden and sources of specific foodborne diseases in nine states [http://www.cdc.gov/foodnet].

Campylobacter

Campylobacter species typically cause mild to moderate infections but occasionally can cause severe infections, particularly in infants, elderly, or immunocompromised persons. Antimicrobial agents are usually not essential in the treatment of Campylobacter infections, but may be life-saving in the case of severe infections. Fluoroquinolones (i.e., ciprofloxacin) are commonly used in the treatment of adults with acute gastroenteritis, including patients with Campylobacter infections.

NARMS has been used to monitor the prevalence of fluoroquinolone-resistant Campylobacter in the United States since 1997. The emergence of fluoroquinolone resistance among Campylobacter is an example of antimicrobial resistance resulting from the use of antimicrobial agents in food animals and the subsequent transfer via the food supply of resistant bacteria to humans. Fluoroquinolones were approved for human medicine in 1986. A national prospective study of reported Campylobacter cases between 1989 and 1990 found no Campylobacter jejuni isolates to be resistant to fluoroquinolones. The first fluoroquinolones approved for use in food animals in the United States were sarafloxacin in 1995 and enrofloxacin in 1996. These fluoroquinolones were approved for the treatment of respiratory disease in chickens and turkeys. A study conducted in Minnesota reported that resistance of human Campylobacter jejuni infections to nalidixic acid, an elementary quinolone, increased from 1% in 1992 to 10% in 1998; among Campylobacter jejuni isolates, there is a close correlation between isolates that are resistant to nalidixic acid and isolates that are resistant to fluoroquinolones. Nalidixic acid-resistant infections that were domestically acquired increased significantly from 1996 through 1998, a finding that was temporally associated with the licensure of fluoroquinolones for use in poultry in 1995. Molecular subtyping of human isolates and domestic chicken products from retail stores in Minnesota showed a significant association between resistant Campylobacter jejuni strains from chickens and domestically acquired infections in residents. Testing of 1997 NARMS Campylobacter jejuni isolates at CDC found fluoroquinolone resistance among 12% of the isolates; this prevalence increased to 18% of isolates in 2001.

In a case-control study of fluoroquinolone-resistant Campylobacter infections conducted in the FoodNet sites, 58% of resistant infections were acquired domestically (Kassenborg et al., unpublished data). When domestically acquired fluoroquinolone-resistant Campylobacter cases were compared with well controls, cases were 10 times more likely to have eaten poultry cooked at a commercial establishment. Because chicken
is not imported into the United States, this observation supports the conclusion that poultry is the dominant source of domestically acquired fluoroquinolone-resistant Campylobacter infections in the United States. In a recent risk assessment, the FDA concluded that the use of fluoroquinolones in chickens in the United States has compromised the treatment with fluoroquinolones of almost 10,000 people a year; meaning that each year, thousands of people with Campylobacter infections seek medical care and are treated with fluoroquinolones, but their infection is already fluoroquinolone resistant.

Salmonella

In addition to fluoroquinolone-resistant Campylobacter, there is also the potential for an emergence of domestically acquired fluoroquinolone-resistant Salmonella in the United States. Antimicrobial agents are commonly used empirically for treatment of patients with Salmonella infections and may be life-saving for patients with invasive infections. Fluoroquinolones are the most commonly used antimicrobial agent for the treatment of invasive Salmonella infections in adults. Although few non-Typhi Salmonella isolates in NARMS from 1996 to 2001 were resistant to fluoroquinolones (MIC ≥ 4 μg/mL), 1% of isolates in 2001 had a decreased susceptibility to fluoroquinolones (MIC ≥ 0.25 μg/mL), an increase from 0.4% in 1996. Salmonella isolates with decreased susceptibility to fluoroquinolones (but that are not resistant to fluoroquinolones) commonly have a single point mutation in a chromosomal gene. Salmonella isolates with decreased susceptibility to fluoroquinolones are of immediate concern because such isolates typically only require a single additional point mutation to become resistant and therefore represent a potential reservoir for the emergence of resistant Salmonella should such isolates be exposed to continued selective pressure. Furthermore, patients infected with Salmonella strains with a decreased susceptibility to fluoroquinolones may respond poorly to treatment with fluoroquinolones and have been associated with apparent treatment failures.

Third-generation cephalosporins, such as ceftriaxone, are commonly used for treatment of invasive Salmonella infections in children because of their pharmacodynamic properties and low prevalence of resistance to these agents. Therefore, there is concern about the potential emergence of ceftriaxone-resistant Salmonella. The first reported case of domestically acquired ceftriaxone-resistant Salmonella was in a 12-year-old child in Nebraska. Investigation by public health officials revealed that the child lived on a farm and his father was a veterinarian. Before the child’s illness, the father was treating several cattle herds for outbreaks due to culture-confirmed Salmonella infection. Although no information was available regarding the use of antimicrobial agents among the infected herds, a third-generation cephalosporin, cefotiofur, is widely used in cattle. Ceftriaxone-susceptible and ceftriaxone-resistant Salmonella were isolated from ill cattle treated by the veterinarian. Both ceftriaxone-resistant and ceftriaxone-susceptible cattle isolates and the ceftriaxone-resistant isolate from the child had similar genetic structures as determined by pulsed-field gel electrophoresis (PFGE). These similar molecular “fingerprints” and their temporal isolation suggest that ceftriaxone resistance emerged in the cattle herds, probably following use of ceftriaxone or other antibiotics that would have selected for and maintained the ceftriaxone-resistant determinant within the intestinal flora of the involved herds.

The Nebraska child’s ceftriaxone-resistant infection was not an isolated event. The percentage of non-Typhi Salmonella isolates in NARMS resistant to ceftriaxone increased over 20-fold from 0.1% in 1996 to 2% in 2001. When patients from whom isolates were received in 1996–1998 were interviewed, few reported international travel, suggesting that most infections were domestically acquired. Furthermore, ceftriaxone resistance in most domestically acquired infections, including the infection in the child in Nebraska, is due to a unique AmpC-type resistance gene (CMY-2), which resides on a plasmid. The finding of a similar molecular mechanism of resistance among different Salmonella strains supports horizontal dissemination of a resistance determinant. A 1999 study at the University of Iowa found multidrug-resistant cephalosporin-resistant bovine, porcine, and human Salmonella isolates from the same geographic region. All human and animal resistant isolates encoded a CMY-2 AmpC-like gene.

The emergence of multidrug-resistant Salmonella Typhimurium definitive type 104 (DT104) in the United States and the United Kingdom, which is resistant to amoxicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline (ACSSuT), is an example of how a highly resistant clone of Salmonella has the ability to spread effectively among animals and then to humans. Described in 1998 by Glynn et al., the emergence of S. Typhimurium DT104 in the United States can be traced back to as early as 1985. The prevalence of Typhimurium isolates with the five-drug pattern of resistance increased from 0.6% in 1979–1980 to 34% in 1996. This strain remains common; among Typhimurium isolates submitted to NARMS, the prevalence of the ACSSuT resistance pattern was 29% in 2001.

Another multidrug-resistant Salmonella that has emerged recently in the United States has been named MDR-AmpC Salmonella Newport. This multidrug-resistant strain is resistant to amoxicillin, chloramphenicol, streptomycin, sulfamethoxazole, and tetracycline (ACSSuT), and apparently has acquired the CMY-2 AmpC-like gene conferring additional resistance to cephalothin, amoxicillin-clavulanic acid, cefotaxin, and cefotiofur. Of Salmonella Newport isolates submitted to NARMS in 2001, a remarkable 25% are MDR-AmpC Salmonella Newport.

Commensal bacteria

Pathogenic bacteria, such as Campylobacter and Salmonella, are not the only concern when considering antimicrobial resistance in bacteria with food animal reservoirs. Commensal bacteria, which are naturally occurring host flora, constitute an enormous potential reservoir of resistance genes for pathogenic bacteria. The prevalence of antibiotic resistance in the commensal bacteria of humans and animals is considered to be a good indicator of the selective pressure of antibiotic usage and reflects the potential for resistance in future infections.

Most resistant bacteria have mobile genetic elements such as R plasmids and transposons. As the reservoir of resistant commensal bacteria increases, the plasmid reservoir becomes larger and enables more frequent transfer of resistance to pathogenic bacteria including Salmonella and Shigella. Escherichia coli,
which is the predominant isolate of aerobic fecal flora in humans and most animals, has demonstrated its ability to transfer resistance genes to other species, including pathogenic bacteria.\(^8,12,29,43,50,54\)

Recent studies have shown an emerging resistance in *E. coli* to fluoroquinolones and third-generation cephalosporins. A study by Garau et al. demonstrated an increase in quinolone resistance among *E. coli* isolates in Spain from 9% to 17% over the course of 5 years. This study also showed a high prevalence of quinolone-resistant *E. coli* in healthy children and adults (26% and 24%, respectively) that could not be explained by previous use of quinolones. Animal testing from slaughterhouses in the area found a high rate of quinolone-resistant *E. coli* in swine and chickens (45% and 90%, respectively).\(^{50}\) Winokur et al. found 16% of clinical *E. coli* isolates from cattle and swine and 1% of clinical human *E. coli* isolates collected in Iowa to be resistant to extended-spectrum cephalosporins. This study also identified identical CMY-2 genes in resistant isolates from both humans and animals, suggesting transfer of the resistance gene between food animals and humans.\(^{62}\)

Other examples of animal-to-human transfer of resistant commensal bacteria are high-level gentamicin-resistant enterococci and quinupristin/dalfopristin-resistant *Enterococcus faecium*. In the United States, gentamicin is commonly used in chickens and turkeys for prevention of early chick mortality, occasionally used in swine for treatment, and seldom used in cattle. The molecular mechanism for resistance for high-level gentamicin-resistant enterococci isolates isolated from food animals on farms, meat and poultry purchased from grocery stores, and from human stool specimens were evaluated.\(^{18}\) Although much heterogeneity was evident, indistinguishable isolates were identified from food animals, meat and poultry, and humans, providing evidence of the spread of gentamicin-resistant enterococci from animals to humans through the food supply.

Quinupristin/dalfopristin (Synercid\(^8\)) was approved for use in humans in 1999 for treatment of vancomycin-resistant *E. faecium* infections. However, virginiamycin, an analog of quinupristin/dalfopristin that is cross-resistant, has been used as a growth promoter in food animals in the United States since 1974.\(^{15,47}\) A study conducted by the CDC in 1998–1999, before the approval of Synercid\(^8\) use in humans, found quinupristin/dalfopristin-resistant *E. faecium* on 58% of chickens purchased in grocery stores from four different states. Additionally, quinupristin/dalfopristin-resistant *E. faecium* was found in 1% of the stools from nonhospitalized people who submitted a stool specimen to clinical laboratories.\(^{18}\) Similar data in Europe led the European Union to ban the subtherapeutic use of virginiamycin in food animals in 1998.\(^{59}\) These findings suggest virginiamycin use in chickens has created a large reservoir of quinupristin/dalfopristin-resistant *E. faecium*. The high carriage of quinupristin/dalfopristin-resistant *E. faecium* on chickens in grocery stores, and the frequent handling of chicken from grocery stores by consumers, suggests that humans are commonly exposed to these resistant bacteria. The use of quinupristin/dalfopristin in humans for the treatment of vancomycin-resistant *E. faecium* and other serious infections may contribute additional selective pressure leading to an increased prevalence of quinupristin/dalfopristin resistance in humans.

### CLINICAL IMPLICATIONS

Human health consequences of increasing antimicrobial resistance in foodborne bacteria include an increase in foodborne illnesses and an increase in number of treatment failures. Mechanisms for these human health consequences are well described in a recent review.\(^7\) Increased human infections of resistant foodborne pathogens occur as the prevalence of resistance increases and as humans are exposed to antimicrobial agents. Taking an antimicrobial may lower the infectious dose for *Salmonella* and potentially other foodborne bacteria, if the pathogen is resistant to that antimicrobial.\(^8\) Analyses of antimicrobial-resistant *Salmonella* outbreaks have demonstrated that previous exposure to antimicrobials can result in a larger number of cases than would have occurred if the outbreak had been caused by a sensitive strain.\(^{13}\) Bohnhoff et al. showed in the early 1960s that mice with an “undisturbed” normal intestinal flora have a *Salmonella* infectious dose of about 10\(^6\) organisms.\(^9\) When they “disturbed” the normal flora by administering streptomycin, the infectious dose for streptomycin-resistant *Salmonella* decreased to only 10 organisms. In *Salmonella* outbreaks, it has been observed that preceding, unrelated treatment with an antimicrobial can predispose humans to infection with resistant\(^{28,49,53}\) or susceptible *Salmonella*.\(^{16}\) Similarly, in studies of sporadic salmonellosis, preceding treatment with an antimicrobial was a risk factor for a resistant infection compared to susceptible infections.\(^{24,37,48}\) Physicians should be aware that, as foodborne pathogens become increasingly resistant, treating patients with antimicrobials, regardless of the reason, increases the risk for that patient to develop a subsequent infection caused by resistant foodborne bacteria. The public health impact of this potentiation effect is more cases of illness and larger outbreaks.

In addition to causing more human illnesses, increasing antimicrobial resistance in foodborne pathogens may result in treatment failures if the foodborne pathogen is resistant to an antimicrobial used for treatment. As previously described, resistance is emerging to antimicrobials commonly used for treatment of serious *Salmonella* infections, that is, fluoroquinolones in adults and extended-spectrum cephalosporins in children. An example of probable treatment failures was recently described by researchers in Denmark, where a multidrug-resistant *S. Typhimurium DT104* outbreak attributed to contaminated pork was traced back to a swine herd.\(^{51}\) The *Salmonella* isolates from humans and pork samples had decreased susceptibility to fluoroquinolones, and 2 patients who were treated with fluoroquinolones died. An official review of these deaths concluded that decreased susceptibility to fluoroquinolones was a contributing factor.

### CONCLUSION

Given that there is an increasing prevalence of antimicrobial resistance and that this resistance has clinical implications, there is a need for mitigation efforts. Such actions will require collaborative efforts by several partners, including the farming, veterinary, medical, and public health communities. Enhanced surveillance is essential for evaluating and directing these efforts. There is a particular need to establish surveillance of antimicrobial usage in animals.
In the United States, collaborative federal actions to address antimicrobial resistance in agriculture are outlined in the Public Health Action Plan to Combat Antimicrobial Resistance, released in 2001 by an interagency task force. A high-priority action item in this plan is the initiation of surveillance of the quantities of antimicrobial agents used in food animals. The essentiality of surveillance of the quantities of antimicrobial agents used in food animals for interpreting surveillance of antimicrobial resistance and for focusing intervention efforts has been reiterated by several groups, including the World Health Organization. Additional action items in the Public Health Action Plan include improved surveillance, research, and education, and, as a further top-priority item, refining and implementing the FDA’s Framework Document. This Framework Document proposes a modified approval process for antimicrobials used in animals.

It intends to ensure the human safety of antimicrobials used in animals by prioritizing these drugs according to their importance in human medicine. Additionally, it proposes to establish required mitigation actions with increasing resistance and to account for resistance developing from specific animal uses. Education of veterinarians regarding appropriate use of antibiotics has been promoted by the American Veterinary Medical Association (AVMA) with published guidelines for the therapeutic use of antibiotics.

The widespread use of antimicrobial agents in food animals is associated with increasing antimicrobial resistance in foodborne pathogens, which subsequently may be transferred to humans. The transfer of these resistant bacteria or the genetic determinants for resistance causes adverse health consequences in humans by increasing the number of foodborne illnesses and increasing the potential for treatment failures. Similar conclusions have been reached by several independent groups in the United States, including the Alliance of Prudent Use of Antibiotics and the Institute of Medicine. To address this public health problem, overuse and misuse of antimicrobial agents in food animals and humans must be reduced. This will be accomplished by adherence to guidelines for therapeutic use of antimicrobial agents in food animals, and the discontinuation of use of antimicrobial agents with a human analog as growth promotants. Several European countries have already demonstrated the feasibility of such measures and the effectiveness of these interventions to combat antimicrobial resistance and reduce public health risks.
